Angiostrongylus cantonensis and Rat Lungworm Disease in Brazil

Silvana Carvalho Thiengo PhD; Raquel de Oliveira Simões MsC; Monica Ammon Fernandez PhD; and Arnaldo Maldonado Júnior PhD

Abstract
The metastrongyloid nematode genus Angiostrongylus includes 18 species, two of which are relevant from a medical standpoint, Angiostrongylus costaricensis and Angiostrongylus cantonensis. The first was described from Costa Rica in 1971 and causes abdominal angiostrongyliasis in the Americas, including in Brazil. Angiostrongylus cantonensis, first described in 1935 from Canton, China, is the causative agent of eosinophilic meningitis. The natural definitive hosts are rodents, and molluscs are the intermediate hosts. Paratenic or carrier hosts include crabs, freshwater shrimp, amphibians, flatworms, and fish. Humans become infected accidentally by ingestion of intermediate or paratenic hosts and the parasite does not complete the life cycle as it does in rats. Worms in the brain cause eosinophilic meningitis. This zoonosis, widespread in Southeast Asia and the Pacific islands, has now been reported from other regions. In the Americas there are records from the United States, Cuba, Jamaica, Brazil, Ecuador, and Haiti. In Brazil seven human cases have been reported since 2007 from the southeastern and northeastern regions. Epidemiological studies found infected specimens of Rattus norvegicus and Rattus rattus as well as many species of molluscs, including the giant African land snail, Achatina fulica, from various regions of Brazil. The spread of angiostrongyliasis is currently a matter of concern in Brazil.

Achatina fulica, Angiostrongylia, Brazil, Eosinophilic meningitis, Rattus norvegicus, Rattus rattus, Snails

Introduction
The metastrongyloid nematode Angiostrongylus cantonensis causes eosinophilic meningitis (and meningoencephalitis) in humans. This parasite, widespread in Southeast Asia and some Pacific islands, has now dispersed to other regions, including Latin America. The spread of this emerging zoonosis is correlated with increased tourism, commerce, and the diversification of habits and customs in certain countries, factors that have facilitated the dispersal of the definitive and intermediate hosts of A. cantonensis. In addition, the introduction of non-native molluscs plays an important role, as has been observed with the giant African snail, Achatina fulica, in Brazil and the South American freshwater snail Pomacea canaliculata in China. Species of Angiostrongylus can infect domestic dogs and wild mammals, as well as humans, as accidental hosts, causing parasitic diseases. Besides A. cantonensis, another congeneric species, A. costaricensis, described from Costa Rica in 1971, is important from a public health standpoint as the causative agent of abdominal angiostrongyliasis, a zoonosis recorded from the south of the United States to northern Argentina. In Costa Rica up to 500 human cases are reported annually. In Brazil cases have been reported mainly in the southern States. This paper focuses on A. cantonensis in Brazil.

Taxonomy
Attempts to organize the family Angiostrongylidae into genera and subgenera, based on the morphology of the rays of the caudal bursa and on the host species, have divided the scientific community, particularly in relation to the important human parasites, ie, A. cantonensis and A. costaricensis. Dougherty synonymized the following genera with Angiostrongylus: Haemastromastrongylus, Parastron, Pulmonema, Cardionema, and Rodentocaulus. Subsequently, Skrjabin et al. recognized four genera, accepting Dougherty’s synonyms, with the exception of Rodentocaulus, which was retained as a valid genus along with two additional more recently described genera that were also considered valid, Rattostrongylus and Angiocaulus. Yamaguti accepted the systematic arrangement proposed by Skrjabin et al.

In 1970 Drozdz proposed dividing the genus Angiostrongylus into two subgenera: Angiostrongylus (Angiostrongylus) with Haemastromastrongylus, Cardionema, and Angiocaulus as synonyms; and Angiostrongylus (Parastron) with Rodentocaulus, Pulmonema, and Rattostrongylus as synonyms. Chabaud abolished the subgenera, and recognized four genera: Angiostrongylus (with synonyms Haemastromastrongylus, Cardionema, and Angiocaulus), Parastron, Rodentocaulus, and his newly created genus Morerostrongylus. However, Anderson adopted the subgeneric classification of Drozdz, with Morerostrongylus as a synonym of Parastron, which was treated as a subgenus of Angiostrongylus, but with the exception of recognizing Rodentocaulus as a distinct valid genus.

In 1986, Ubelaker reorganized the family Angiostrongylidae, recognizing the genera Angiostrongylus (synonym Haemastromastrongylus), Parastron, Pulmonema, Rattostrongylus, Morerostrongylus, Cardionema, Angiocaulus (synonym Cardionema), Rodentocaulus, Galestrostrongylus (synonym Thastrongylus), and Stefanskostrongylus. Although this is the most recent taxonomic revision of the Angiostrongylidae, based on morphological similarity of the bursal rays and host animals, it has not been widely accepted, since, for instance, few people use Parastron for A. cantonensis. Too few molecular data are available to help resolve the systematics of the family.

Based on the classification of Dougherty, we recognize 18 species of Angiostrongylus from around the world (excluding those albeit nomenclaturally valid species that have been described on the basis only of female morphology). Angiostrongylus vasorum, A. raiili, A. gubernaculatus, and A. chabaudi have carnivores as their definitive hosts. The remaining 14 species have rodents as definitive hosts: A. taterone, A. cantonensis, A. sciuri, A. mackerrasae, A. sandarsae, A. petrowi, A. dufardini, A. Schmidtii, A. costaricensis, A. malaysiensis, A. ryjikovi, A. siamensis, A. morerai, and A. lenzii.
**Angiostrongylus cantonensis** was originally described in the genus *Pulmonema* from specimens recovered from the lungs of naturally infected rats (*Rattus norvegicus* and *Rattus rattus*) from Canton, China.¹⁷ The adult worms (Figure 1) are characterized by a filiform body in both sexes, tapering at the anterior end. Females are larger and more robust than males. Detailed morphological descriptions have been published elsewhere¹⁸,¹⁹

**Life Cycle and Hosts**

The life cycle of *A. cantonensis* involves various species of terrestrial and freshwater gastropods as intermediate hosts and rats as definitive hosts.²⁰⁻²³ As *A. cantonensis* occurs in the adult stage in the pulmonary arteries of the definitive hosts, commonly *Rattus rattus* and *R. norvegicus*, it is known as the rat lungworm. In experimental infection of *R. norvegicus*, the female worm lays eggs inside the pulmonary arteries, where they develop into the first-stage larvae (*L₁*), which then move to the interior of the alveoli. The larvae then migrate to the pharynx and are swallowed, pass through the gastrointestinal tract, and are eliminated in the feces.²¹,²⁴ Land or freshwater snails are the principal intermediate hosts, and become infected either by ingestion of *L₁* in the rat feces or by penetration of these larvae through the body wall or respiratory pore.²⁵ In the mollusc tissue the *L₁* molts twice (*L₂* and *L₃*) and the period necessary for the development is around 20 days. The worms become infected mainly by the ingestion of intermediate hosts infected by *L₁* larvae. These larvae then penetrate the intestinal wall and enter the bloodstream a few hours after being ingested. They reach the pulmonary circulation from the heart and are dispersed to various other organs by the arterial circulation. Many reach the brain and molt again, becoming *L₅* larvae. The fifth molt into the subadult stage (*L₄*) occurs in the subarachnoid space, from where, after developing further, they migrate to the pulmonary arteries where they are found 25 days after infection. The worms then reach sexual maturity at around 35 days and the *L₅* larvae can be found in the rodent’s feces about 42 days after the exposure to the previous generation of *L₁* larvae.

Infection in humans occurs when they eat raw or undercooked snails and slugs, or paratenic hosts, including land crabs, freshwater shrimp, fish, frogs, and planarians.²⁶ In humans, the young larvae reach the brain, where they die rather than migrating further and completing their development. This causes eosinophilic meningitis (or meningoencephalitis), which has neurological symptoms. Usually the infection does not kill the victim, except when there is massive exposure to infective *L₁* larvae.²⁷

The parasite displays broad specificity for intermediate hosts; many species of terrestrial and freshwater molluscs have been found naturally infected, including *Achatina fulica*, *Bradybaena similis*, *Subulina octona*, *Pomacea canaliculata*, *Pomacea lineata*, other *Pomacea* species, *Deroceras laeve*, and species of *Pila*.³,¹⁸,²³,²⁸ It has been found in various paratenic hosts, and although these are passive hosts in which the parasite does not undergo any development, they play an important role as they increase the opportunities for the parasite to infect definitive hosts.

In southern China, an apple snail species, *Pomacea canaliculata*, and the giant African snail, *Achatina fulica*, both non-native, are widespread and the number of cases of eosinophilic meningitis has been increasing, the transmission being linked to both species. Most recently, serious outbreaks have been reported, in most cases directly related to consumption of *P. canaliculata*.⁶⁻²⁹

**Angiostrongylus cantonensis and Angiostrongyliasis in Brazil**

Sporadic outbreaks of eosinophilic meningitis caused by *A. cantonensis* were first reported in the Americas in the latter part of the twentieth century.³⁰ The zoonosis, or at least infected rodents, have now been reported in the Americas and islands of the Caribbean from the United States,³¹ Cuba,³²,³³ Jamaica,³⁴ Brazil,³,⁴,²⁶ Ecuador,³⁵ and Haiti.³⁶

The first report of this zoonosis in Brazil was in the municipality of Cariacica, Espírito Santo State,³ with subsequent reports from two municipalities (Olinda and Escada) in Pernambuco State,³⁶,²⁸ and in the city of São Paulo, São Paulo State.³⁷ In the first two states naturally infected definitive and/or intermediate hosts had been discovered during the epidemiological investigation of the human cases. *Achatina fulica* was considered the vector in three of the four reported cases.³,¹⁸,²⁶ One of the cases in Pernambuco State was attributed to ingestion of undercooked apple snails (*Pomacea lineata*).³⁸ Specimens of *A. fulica* have been found infected with *A. cantonensis* larvae in south and southeastern Brazil since 2007 and more recently from Pará State in the Amazon region, northern Brazil.³⁹ A species of *Pomacea* was also associated with an outbreak of eosinophilic meningitis in Ecuador.⁴⁵

Natural infection of definitive vertebrate hosts with *A. cantonensis* has also been reported in Brazil. Infected *Rattus rattus* and *R. norvegicus* have both been found in Pará State⁴⁶ and infected *R. norvegicus* have also been reported in the States of Rio de Janeiro (southeastern Brazil)⁴⁷ and Rio Grande do Sul (southern Brazil), according to Carlos Graeff-Teixeira (oral communication, June 2012). Some reports of infected rodents in urban areas were associated with epidemiological investigations following the occurrence of cases of eosinophilic meningitis.³⁹ The prevalence of *A. cantonensis* in rodents is highly variable⁴⁸ and does not suggest specificity among species in the genus *Rattus*.

How *A. cantonensis* arrived and became established in the Americas is not well understood, although Diaz⁴⁰ attributed its introduction to introduction of *Rattus norvegicus* in shipping containers. Its introduction to Brazil has been postulated as either with parasitized rats during the country’s colonial period (1500-1822), when there was frequent contact with Africa and Asia⁴¹ and/or by recent invasion of the giant African snail, *A. fulica*, which began in the 1980s.⁴¹,⁴² As Brazil is currently experiencing the explosive phase of the invasion of *A. fulica*, which has now been recorded in 25 of the 26 states and in the Federal District (Figure 2), the emergence of eosinophilic meningitis is a matter of concern.⁴¹,⁴² although many species of molluscs may act as intermediate hosts in Brazil.⁴¹
Conclusion
The spread of *Angiostrongylus cantonensis* in Brazil is a matter of public health concern because of the widespread occurrence of infected rats and snails in peridomestic areas. There is a need for education of the population regarding disease transmission and prevention. Physicians should be made more aware of the possibility of *A. cantonensis* infection. And serological diagnosis of angiostrongyliasis should be available to facilitate appropriate medical treatment. Control and monitoring of intermediate and definitive hosts in areas of epidemiological relevance should be undertaken to limit the occurrence of new transmission foci.
